Exercise 13

1 Self-stabilizing Spanning Tree

In this exercise, we are searching for efficient, self-stabilizing spanning tree algorithms. Thus, the spanning tree will be adapted if the topology changes or nodes and/or links fail.

a) Prove an (asymptotically) optimal lower bound on the time complexity of any self-stabilizing spanning tree algorithm!

b) If the transformation from the lecture is applied to the Bellman-Ford BFS algorithm (Algorithm 14), is the time complexity of the resulting self-stabilizing algorithm optimal? On average, how much more information per round must be transmitted compared to the original algorithm?

c) Assume that the diameter D is known to the leader (i.e., the root of the constructed tree) Can you give an algorithm stabilizing—up to constant factors—in the same time, but sending not more information in each round than the unmodified Bellman-Ford algorithm? If yes, can your approach be generalized to other algorithms? If no, prove a corresponding lower bound!
