Overview

- · Capacity and Related Issues
- Protocol vs. Physical Models
- Capacity in Random Network Topologies
- Achievable Rate of Sensor Networks
- Scheduling Arbitrary Networks

Fundamental Questions

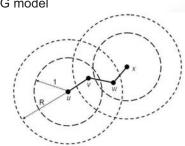

- How much communication can you have in a wireless network?
- · How long does it take to meet a given communication demand?
- · How much spatial reuse is possible?
- What is the capacity of a wireless network?
- Many modeling issues are connected with these questions.
- You can ask these questions in many different ways that all make perfect sense, but give different answers.
- In the following, we look at a few results in this context, unfortunately only superficially.

Ad Hoc and Sensor Networks - Roger Wattenhofer - 11/5

Protocol Model

- For lower layer protocols, a model needs to be specific about interference. A simplest interference model is an extension of the UDG. In the protocol model, a transmission by a node in at most distance 1 is received iff there is no conflicting transmission by a node in distance at most R, with R ≥ 1, sometimes just R = 2.
- + Easy to explain
- Inherits all major drawbacks from the UDG model
- Does not easily allow for designing distributed algorithms/protocols
- Lots of interfering transmissions just outside the interference radius R do not sum up
- Can be extended with the same extensions as UDG, e.g. QUDG

Motivation

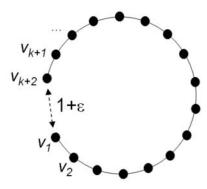

- Spatial capacity is an indicator of the "data intensity" in a transmission medium.
- The capacity of some well-known wireless technologies
 - IEEE 802.11b 1,000 bit/s/m²
 - Bluetooth 30,000 bit/s/m²
 - IEEE 802.11a 83,000 bit/s/m²
 - Ultra-wideband 1,000,000 bit/s/m²
- The wireless capacity is a function of the physical layer characteristics such as available bandwidth or frequency, but also how well the protocols on top of the physical layer are implemented, in particular media access. As such capacity is a theoretical framework for MAC protocols.

Ad Hoc and Sensor Networks – Roger Wattenhofer – 11/6

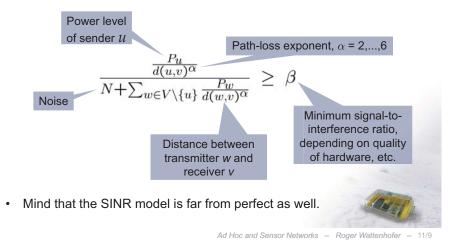

Hop Interference (HI)

- An often-used interference model is hop-interference. Here a UDG is given. Two nodes can communicate directly iff they are adjacent, and if there is no concurrent sender in the *k*-hop neighborhood of the receiver (in the UDG). Sometimes *k* = 2.
- Special case of the protocol model, inheriting all its drawbacks
- + Simple
- + Allows for distributed algorithms
- A node can be close but not produce any interference (see picture)
- Can be extended with the same extensions as UDG, e.g. QUDG

Physical (SINR) Model

- We look at the signal-to-noise-plus-interference (SINR) ratio.
- Message arrives if SINR is larger than β at receiver

More on SINR

- Often there is more than a single threshold β , that decides whether reception is possible or not. In many networks, a higher S/N ratio allows for more advanced modulation and coding techniques, allowing for higher throughput (e.g. Wireless LAN 802.11)
- However, even more is possible: For example, assume that a receiver is receiving two transmissions, transmission T_1 being much stronger than transmission T_2 . Then T_2 has a terrible S/N ratio. However, we might be able to "subtract" the strong T_1 from the total signal, and with $T T_1 = T_2$, and hence also get T_2 .
- These are just two examples of how to get more than you expect.

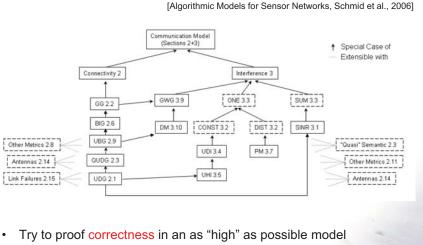

SINR Discussion

- + In contrast to other low-layer models such as PM the SINR model allows for interference that does sum up. This is certainly closer to reality. However, SINR is not reality. In reality, e.g., competing transmissions may even cancel themselves, and produce less interference. In that sense the SINR model is pessimistic (interference summing up) and optimistic (if we remove the "I" from the SINR model, we have a UDG, which we know is not correct) at the same time.
- SINR is complicated, hard to analyze
- Similarly as PM, SINR does not really allow for distributed algorithms
- Also, in reality, e.g. the signal fluctuates over time. Some of these issues are captures by more complicated fading channel models.

```
Ad Hoc and Sensor Networks – Roger Wattenhofer – 11/10
```

Model Overview

- For efficiency, a more optimistic ("lower") model is fine
- Lower bounds should be proved in "low" models.

Measures for Network Capacity

Throughput capacity

- Number of successful packets delivered per time
- Dependent on the traffic pattern
- E.g.: What is the maximum achievable, over all protocols, for a random node distribution and a random destination for each source?

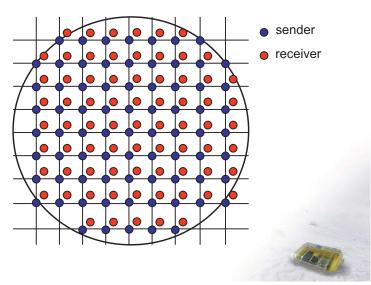

· Transport capacity

- Network transports one bit-meter when one bit has been transported a distance of one meter
- Number of bit-meters transported per second
- What is the maximum achievable, over all node locations, and all traffic patterns, and all protocols?

Ad Hoc and Sensor Networks – Roger Wattenhofer – 11/13

Transport Capacity: Example

Ad Hoc and Sensor Networks – Roger Wattenhofer – 11/15

Transport Capacity

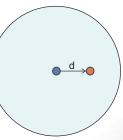

- *n* nodes are arbitrarily located in a unit disk
- We adopt the protocol model with R=2, that is a transmission is successful if and only if the sender is at least a factor 2 closer than any interfering transmitter. In other words, each node transmits with the same power, and transmissions are in synchronized slots.
- What configuration and traffic pattern will yield the highest transport capacity?
- Idea: Distribute *n*/2 senders uniformly in the unit disk. Place the *n*/2 receivers just close enough to senders so as to satisfy the threshold.

```
Ad Hoc and Sensor Networks – Roger Wattenhofer – 11/14
```

Transport Capacity: Understanding the example

- Sender-receiver distance is $\Theta(1/\sqrt{n})$. Assuming channel bandwidth W [bits], transport capacity is $\Theta(W\sqrt{n})$ [bit-meter], or per node: $\Theta(W/\sqrt{n})$ [bit-meter]
- Can we do better by placing the sourcedestination pairs more carefully? Not really: Having a sender-receiver pair at distance *d* inhibits another receiver within distance up to 2*d* from the sender. In other words, it kills an area of $\Theta(d^2)$.

- We want to maximize *n* transmissions with distances *d*₁, *d*₂, ..., *d*_n given that the total area is less than a unit disk. This is maximized if all *d_i* = Θ(1/√n). So the example was asymptotically optimal.
 - BTW, a fun geometry problem: Given k circles with total area 1, can you always fit them in a circle with total area 2?

More capacities...

- The throughput capacity of an *n* node random network is $\Theta(\frac{W}{\sqrt{n\log n}})$
- There exist constants c and c' such that $\lim_{n \to \infty} \Pr[c \frac{W}{\sqrt{n \log n}}$ is feasible]=1

$$\lim_{n \to \infty} \Pr[c' \frac{W}{\sqrt{n \log n}} \text{ is feasible}] = 0$$

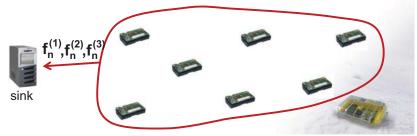

- Transport capacity:
 - Per node transport capacity decreases with $\frac{1}{\sqrt{n}}$
 - Maximized when nodes transmit to neighbors
- Throughput capacity:
 - For random networks, decreases with $\frac{1}{\sqrt{n \log n}}$
 - Near-optimal when nodes transmit to neighbors
- In one sentence: local communication is better...

Ad Hoc and Sensor Networks – Roger Wattenhofer – 11/17

Data Gathering in Wireless Sensor Networks

- Data gathering & aggregation
 - Classic application of sensor networks
 - Sensor nodes periodically sense environment
 - Relevant information needs to be transmitted to sink
- Functional Capacity of Sensor Networks
 - Sink peridically wants to compute a function f_n of sensor data
 - At what rate can this function be computed?

Ad Hoc and Sensor Networks - Roger Wattenhofer - 11/19

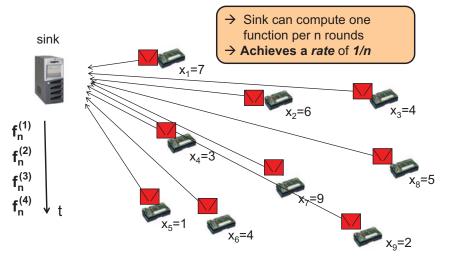

Even more capacities...

- · Similar claims hold in the physical [SINR] model as well...
- Results are unchanged even if the channel can be broken into subchannels
- There are literally thousands of results on capacity, e.g.
 - on random destinations
 - on power-law traffic patterns (probability to communicate to a closer node is higher)
 - communication through relays
 - communication in mobile networks
 - this research area has been quite a hobby of information theorists.
- Problem: The model assumptions are sometimes quite optimistic, if not unrealistic...
- What is the capacity of non-random networks?

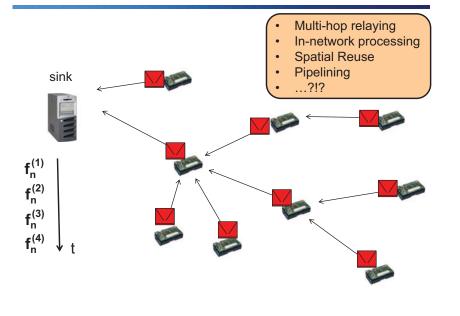

Ad Hoc and Sensor Networks – Roger Wattenhofer – 11/18

The Simple Round-Robin Scheme

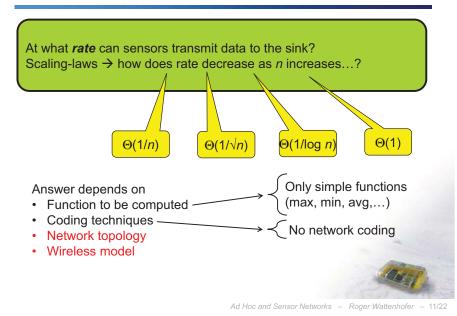

• Each sensor reports its results directly to the sink (one after another).

Is there a better scheme?!?

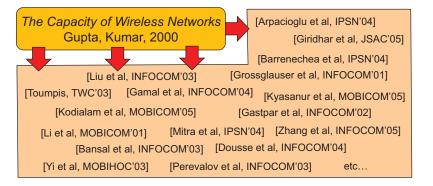

Capacity in Wireless Sensor Networks

Practical relevance?

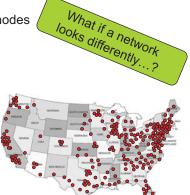

- Efficient data gathering!
- Efficient MAC layer!
- This (and related) problem is studied theoretically:

Network Topology?

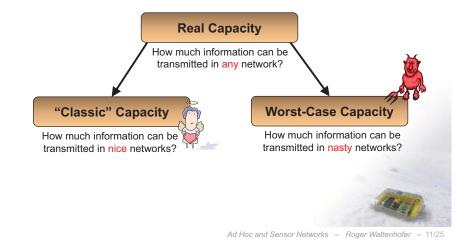

- Almost all capacity studies so far make very strong assumptions
 on node deployment, topologies
 - randomly, uniformly distributed nodes
 - nodes placed on a grid
 - etc.

Capacity for Arbitrary/Worst-Case Network Topologies

- What can one say about worst-case node distributions?
- · What can one say about arbitrary node distributions?

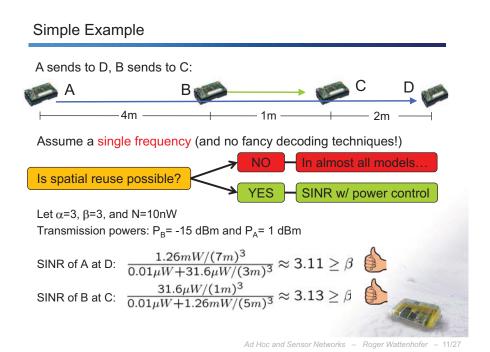

Wireless Models

- Several models for wireless communication
 - Connectivity-only models (e.g. UDG, QUDG, BIG, UBG, etc.)
 - Interference models
 - Protocol models
 - Two Radii model with constant power (e.g. UDG with interference radius R=2).
 - Nodes may use power control (transmission and interference disks of different size)
 - Physical models
 - SINR with constant power (every node transmitting with the same power)
 - SINR with power control (nodes can choose power)
 - Etc.
- Premise: Fundamental results should not depend on model!
 - And indeed, classical capacity (assuming e.g. random or regular node distribution) results are similar in all the models above
 - Are there any examples where results depend on model?!

 \overline{AC}

Ad Hoc and Sensor Networks – Roger Wattenhofer – 11/26

This works in practice!

[Moscibroda et al., Hotnets 2006]

- Measurements using mica2 nodes!
- Replaced standard MAC protocol by a (tailor-made) "SINR-MAC"
- Measured for instance the following deployment...

• Time for successfully transmitting 20,000 packets:

	Time required			Messages received	
	standard MAC	"SINR-MAC"	1	standard MAC	"SINR-M.
Node u_1	721s	267s	Node u_4	19999	19773
Node u_2	778 <i>s</i>	268s	Node u_5	18784	18488
Node u_3	780 <i>s</i>	270s	Node u_6	16519	19498
Trode 03			i node a ₆	10015	1545
			Created		

Speed-up is almost a factor 3

Worst-Case Rate in Sensor Network: Protocol Model

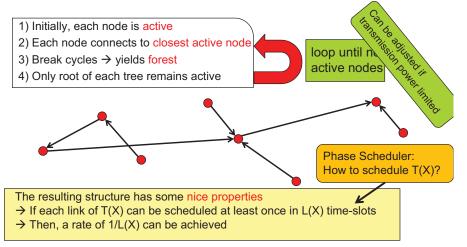

- Topology (worst-case!): Exponential node chain
- Model: Protocol model, with power control
 - Assume for simplicity that the interference radius is twice the transmission radius (however, this can be relaxed easily)

- Whenever a node transmits to another node all nodes to its left are in its interference range. In other words, no two nodes can transmit.
- Network behaves like a single-hop network!
- Same result for SINR with constant power or P ~ d^α.

In the **protocol model**, the achievable rate is $\Theta(1/n)$.

Scheduling Algorithm – High Level Procedure

- High-level idea is simple
- Construct a hierarchical tree T(X) that has desirable properties

Physical Model with Power Control

In the **physical model**, the achievable rate is $\Omega(1/\text{polylog } n)$, independent of the network topology.

- Original result was Ω(1/log³n). [Moscibroda et al, Infocom 2006]
- Later improved to $\Omega(1/log^2n)$. [Moscibroda, IPSN 2007]
- Algorithm is centralized, complex → not practical
- · But it shows that high rates are possible even in worst-case networks
- Basic idea: Enable spatial reuse by exploiting SINR effects.

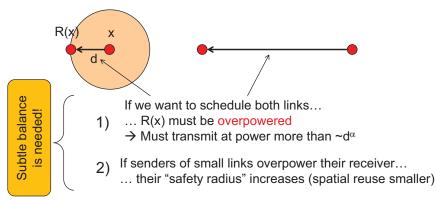

Ad Hoc and Sensor Networks – Roger Wattenhofer – 11/30

Scheduling Algorithm – Phase Scheduler

- How to schedule T(X) efficiently
- We need to schedule links of different magnitude simultaneously!
- Only possibility:

senders of small links must overpower their receiver!

Scheduling Algorithm – Phase Scheduler

- 1) Partition links into sets of similar length small
- 2) Group sets such that links a and b in two sets in the same group have at least $d_a \ge (\xi\beta)^{\xi(\tau a - \tau b)} \cdot d_b$

large

Factor 2 between two sets

- \rightarrow Each link gets a τ_{ii} value \rightarrow Small links have large τ_{ii} and vice versa
- \rightarrow Schedule links in these sets in one outer-loop iteration
- \rightarrow Intuition: Schedule links of similar length or very different length
- Schedule links in a group → Consider in order of decreasing length (I will not show details because of time constraints.)

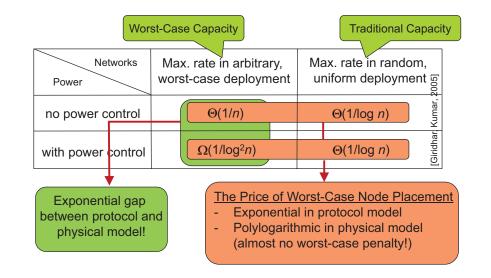

Together with structure of $T(x) \rightarrow \Omega(1/\log^3 n)$ bound

Ad Hoc and Sensor Networks – Roger Wattenhofer – 11/33

Theoretical Implications

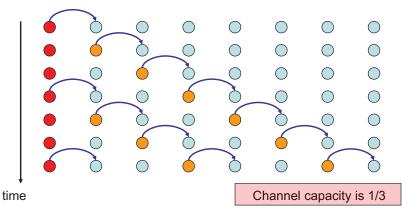

- All MAC layer protocols we are aware of use either uniform or d^α power assignment.
 - Thus, the theoretical performance of current MAC layer protocols is in theory as bad as scheduling every single node individually!
- Faster polylogarithmic scheduling (faster MAC protocols) are theoretically possible in all (even worst-case) networks, if nodes choose their transmission power carefully.
 - Theoretically, there is no fundamental scaling problem with scheduling.
 - Theoretically efficient MAC protocols must use non-trivial power levels!
- Well, the word theory appeared in every line... ☺

Rate in Wireless Sensor Networks: Summary

Possible Applications – Improved "Channel Capacity"

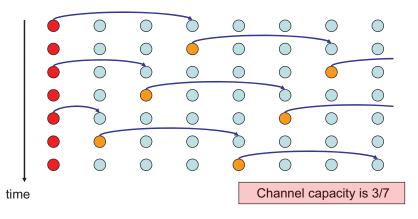

- Consider a channel consisting of wireless sensor nodes
- What is the throughput-capacity of this channel ...?

Ad Hoc and Sensor Networks - Roger Wattenhofer - 11/35

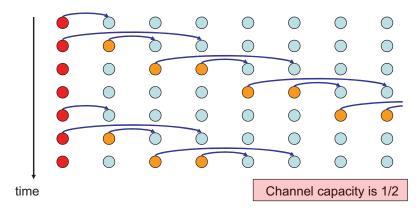

Possible Applications - Improved "Channel Capacity"

- A better strategy...
- Assume node can reach 3-hop neighbor

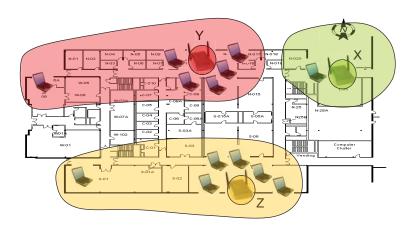

Possible Applications – Improved "Channel Capacity"

- All such (graph-based) strategies have capacity strictly less than 1/2!
- For certain α and β , the following strategy is better!

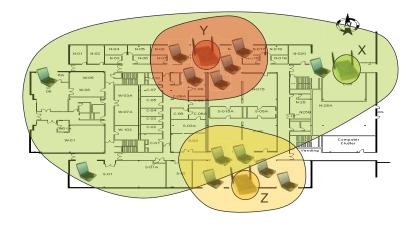

Possible Application – Hotspots in WLAN

Traditionally: clients assigned to (more or less) closest access point
 → far-terminal problem → hotspots have less throughput

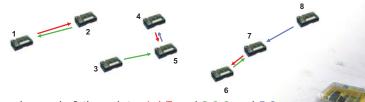

Possible Application – Hotspots in WLAN

- Potentially better: create hotspots with very high throughput
- Every client outside a hotspot is served by one base station
- → Better overall throughput increase in capacity!

Scheduling Arbitrary Links?

- Given: A set of arbitrary communication requests in the plane
 - Each request is defined by position of source and destination
 - Each communication request has the same demand; if some request has a higher demand, just add links between the same sender/receiver
 - Just single-hop, no forwarding at intermediate nodes
 - Model: SINR with constant power
- Goal: Minimize the time to schedule all links!
 - Those scheduled in the same time slot must obey SINR constraints

Example needs 3 time slots: 1,4,7 and 2,3,6 and 5,8

Some Results

- Just checking whether some links can be scheduled in the same time slot is trivial. Simply test the SINR at each receiver.
 - In fact, even with power control this is easy. Since distances are fixed the SINR feasibility boils down to a set of linear equations:

 $\frac{P_{i}}{d_{i}^{\alpha}} \geq \beta (I + \frac{P_{1}}{d_{1}^{\alpha}} + \dots + \frac{P_{i-1}}{d_{i-1}^{\alpha}} + \frac{P_{i+1}}{d_{i+1}^{\alpha}} + \dots + \frac{P_{k}}{d_{k}^{\alpha}}), P_{i} \geq 0, \forall i.$

- On the other hand, scheduling all links in minimum time is difficult (NP-complete), even with constant power. [Goussevskaia et al., 2007]
 With power control, the complexity of scheduling is still unknown.
- What about approximation algorithms? Is it easy to schedule the maximum number of links in one slot? How much time do you need to deliver a given communication demand?

Ad Hoc and Sensor Networks – Roger Wattenhofer – 11/42

One-Slot Scheduling with Fixed Power Levels

- Given a set L={l₁,...,l_n} of arbitrary links, we want to maximize the number of links scheduled in one time-slot
- Constant approximation algorithm:

*Definition: Affectedness is how much interference a link can tolerate, i.e. $a_S(l_v) = 1$ if SINR_S(l_v) = β

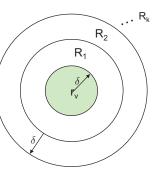

One-Slot Scheduling: Correctness Proof

- We need to prove affectedness $a_S(I_v) \le 1$ for all I_v in S

S_v :set of <i>shorter</i> (≤) links in S, i.e., added <i>before</i> I_v	S _v ⁺ :set of <i>longer</i> (≥) links in S, i.e., added <i>after</i> I _v
$a_{Sv-}(I_v) \le 2/3 \text{ (OK! by algo)}$	$a_{Sv+}(I_v) \le 1/3$ (? See below!)

- All senders in set S_v^+ have pair wise distance $\delta = (c-1)d_{vv}$.
- We partition the space in infinitely many rings of thickness δ .
 - There is no sender in S_v^+ in circle R_0
 - A sender in ring R_k has at least distance k δ
 - The number of senders in ring R_k is O(k)
 - Affectedness from ring R_k is $O(\beta k^{1-\alpha} \delta^{-\alpha})$
 - Total affectness is O(Σ_{k≥1}βk^{1-α}δ^{-α}) ≤ 1/3, for α > 2 and large enough constant
 - $c = f(\alpha, \beta)$

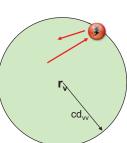

Ad Hoc and Sensor Networks - Roger Wattenhofer - 11/41

One-Slot Scheduling: Approximation Proof

 Count the number of links deleted by ALG that could have been scheduled in the optimum solution OPT: OPT' = OPT \ ALG

	OPT' =	$OPT' = OPT_1 + OPT_2$				
	OPT ₁ : links deleted in step 1		OPT ₂ : links deleted in step 2			
Claim 1: $ OPT_1 \le \rho_1 ALG $, with $\rho_1 = f(c)$						

 Proof: If the optimal wants to schedule more than ρ₁ links around receiver r_ν, then two of these links have to be very close, and would not satisfy the SINR condition (since their length is at least the length of link I_ν).

One-Slot Scheduling: Approximation Proof (Part 2)

- Claim 2: $|OPT_2| \le \rho_2 |ALG|$, $\rho_2 = 10$
 - Proof: Let $B = OPT_2$ (senders) and R = ALG (senders also)
 - Assume for the sake of contradiction that |B| > 10|R|.
 - By the blue dominant centers lemma, there is a 2-blue-dominant point *b* in OPT₂. Since *b* is 2-blue-dominant, it is twice as much affected by OPT₂ than by ALG. (Really, it is the receiver of link I_b that is affected but thanks to the clearing of the neighborhood, the receiver is "close" to the sender; some nasty details omitted).
 - In other words, we have $a_{ALG}(I_b) < \frac{1}{2} \cdot a_{OPT2}(I_b)$. With $a_{OPT2}(I_b) \le 1$ we have $a_{ALG}(I_b) < \frac{1}{2}$. This contradicts that link I_b has been deleted by step 2 of the algorithm, since step 2 only deletes links with $a_S(I_b) \ge 2/3$.
- In summary, $(\rho_1 + \rho_2) \cdot |ALG| \ge |OPT_1| + |OPT_2| = |OPT'| = |OPT \setminus ALG| \ge |OPT| |ALG|$. That is, $|ALG| \ge |OPT| / (\rho_1 + \rho_2 + 1) = \Omega(|OPT|)$.

Helper Lemma: Blue-Dominant Centers Lemma

Consider two disjoint sets *B* and *R* of *blue* and *red* points in the plane.
 If |*B*| > 5q|*R*| then at least one point *b* in *B* is *q*-blue-dominant.

Definition: a point *b* in *B* is *q*-blue-dominant (q in Z^+) if, for every ball of radius *d* around *b*, there are *q* times more blue than red points.

- Proof: for each red point *r* in *R*, remove *q* "guarding sets" of *r*, i.e., *q* times the 5 closest blue points in all directions.
- After processing all the red points, at least one blue point b^* is left, since |B| > 5q|R|. Point b^* is blue-dominant, since all red points in *R* are "guarded" by at least *q* blue points from all directions.

Open problem

- This is an area with more open than closed problems. An obvious open problem is scheduling with power control. Formally, the problem can be defined as follows:
- A communication request consists of a source and a destination, which are arbitrary points in the Euclidean plane. Given *n* communication requests, assign a color (time slot) to each request. For all requests sharing the same color specify power levels such that each request can be handled correctly, i.e., the SINR condition is met at all destinations. The goal is to minimize the number of colors.
- · Pretty much nothing is known about this problem.
